ABSTRACT

We identify two attacks on the Network Time Protocol (NTP)’s cryptographically-authenticated broadcast mode. First, we present a replay attack that allows an on-path attacker to indefinitely stick a broadcast client to a specific time. Second, we present a denial-of-service (DoS) attack that allows an off-path attacker to prevent a broadcast client from ever updating its system clock; to do this, the attacker sends the client a single malformed broadcast packet per query interval. Our DoS attack also applies to all other NTP modes that are ‘ephemeral’ or ‘preemptable’ (including manycast, pool, etc). We then use network measurements to give evidence that NTP’s broadcast and other ephemeral/preemptable modes are being used in the wild. We conclude by discussing why NTP’s current implementation of symmetric-key cryptographic authentication does not provide security in broadcast mode, and make some recommendations to improve the current state of affairs.

1. INTRODUCTION

The Network Time Protocol (NTP) [11], one of the Internet’s oldest protocols, is used to set time on Internet clocks. Time places a crucial and often-ignored role in the security and correctness of computing applications, and especially in cryptographic protocols. As we discussed in [9], an attacker that manipulates time using NTP can seriously undermine the security of key Internet protocols and applications, including TLS certificates [7,12,15], DNSSEC, routing security with the RPKI, authentication with Kerberos, caching, and bitcoin [3]. NTP operates in several modes including (1) client/server, (2) symmetric active/passive, and (3) broadcast/multicast. Our earlier work [9] considered attacks on NTP’s client/server mode. In this companion paper, we consider the security of NTP’s broadcast mode, which is intended for an environment with a few servers and potentially a large client population.

We use network measurements to give evidence that NTP’s broadcast mode is used in the wild by thousands of NTP clients (Section 5). We show that while symmetric-key cryptographic authentication of NTP broadcast traffic is recommended by the NTP specification [11] and required by the open-source NTP reference implementation *ntpd*, it does not provide sufficient protection against attacks on broadcast mode. We consider both (1) on-path attacks, where the attacker occupies a privileged position on the path between NTP client and one of its servers, and (2) off-path attacks, where the attacker can be anywhere on the network and does not observe the traffic between client and any of its servers.

We present an on-path replay attack on authenticated broadcast mode (CVE-2015-7973) that causes the NTP client to get stuck at a particular time (Section 3), and an off-path denial-of-service attack on authenticated broadcast mode (CVE-2015-7979) that also applies to all of NTP’s “preemptable” and “ephemeral” modes of operation (Section 4). Both of these attacks exploit issues in the NTP protocol specification in RFC5905 [11], and have been experimentally verified on *ntpd* v4.2.8p3. We conclude by discussing the inherent challenges of cryptographically authenticating NTP’s broadcast mode, and provide several recommendations for the way forward (Section 6).

Disclosure. These results were disclosed on October 7, 2015 and made public on January 19, 2016. CVE-2015-7973 and CVE-2015-7979 have been assigned, and patches have been added to *ntpd* v4.2.8p6.

2. NTP’S BROADCAST MODE

NTP clients and servers are not configured to operate in broadcast mode by default. However, there is a configuration option that enables broadcast mode.

Broadcast servers. An NTP broadcast server can be preconfigured to periodically send ‘persistent’ broadcast-association server packets (*NTP mode 5 packets*) to the clients on the broadcast network. By persistent, we mean the server mobilizes the broadcast association upon initialization, and never demobilizes the association [11].

Broadcast clients. An NTP client can be preconfigured to accept NTP mode 5 packets.¹(Figure 1 presents a sample broadcast packet.) When a broadcast client receives its first NTP mode 5 packet, the client must first calculate the propagation delay by exchanging a volley of client/server mode packets with the broadcast server—where the client sends the server an NTP mode 3 query and the server responds with an NTP mode 4 response.² After this, the client reverts

¹The configuration option *broadcastclient* or *multicastclient* [*address*] allows an *ntpd* client to receive and process mode 5 broadcast packets.

²The server and client also run the Autokey security protocol, if they are configured to do so. Autokey [6] is public-key authentication method for NTP, but NTP clients do not request Autokey associations by default [1], and many public NTP servers do not support Autokey (*e.g.*, servers in *pool.ntp.org*). In fact, a lead developer of the *ntpd* client wrote in 2015 [17]: “Nobody should be using autokey. Or from the other direction, if you are using autokey you should stop using it.” We therefore do not consider Autokey any further here.

to broadcast client mode, and creates an *ephemeral* association with the server upon receipt of further mode 5 broadcast packets. An *ephemeral* association is mobilized upon arrival of a packet and exists until error or timeout [11].

Authenticating an association. How does an NTP client validate incoming packets before establishing an association with a server? Most NTP traffic (especially client/server-mode traffic) is not cryptographically authenticated.³ However, even in the absence of cryptographic authentication, NTP clients running in client/server mode or symmetric active/passive mode use a *nonce* to validate a server’s response. The nonce is a field in the NTP packet, called the *origin timestamp*; see Figure 1. Upon receipt of an NTP response packet, the client checks if the 64-bit *transmit timestamp* field in the most recent query packet it sent the server, matches the 64-bit *origin timestamp* field in the incoming response packet. This is called *TEST2* in the NTP specifications. This non-cryptographic authentication is based on the premise that the nonce has enough entropy such that an *off-path* attacker, who can not see the NTP packets in transit, cannot guess the nonce. Indeed, as we argued in [9], we can safely assume that this nonce has about 32 bits of entropy, and so it is difficult to forge from off path.

Authenticating broadcast. In contrast to the client/server mode, where the client actively sends a query to the server to get the response, the broadcast client operates in *listen-only* mode. Because the client does not send the server any queries for broadcast packets, the *origin timestamp* field in the broadcast server packet is always set to *null*. So now *TEST2* that defends NTP’s client-server mode from off-path attacks does not apply. Moreover, the most recent NTP reference implementation (ntpd v4.2.8p6) does NOT use UDP source port randomization [8], and so an off-path attacker can easily forge an unauthenticated mode 5 packet.

Also, an NTP client preconfigured to run in broadcast client mode will accept packets from ANY server that sends it broadcast packets; it is NOT configured to listen only to one particular broadcast server. So any off-path attacker can easily send broadcast messages and the client will accept them. RFC5905 [11, pg 57] says:

Filtering can be employed to limit the access of NTP clients to known or trusted NTP broadcast servers. Such filtering will prevent malicious traffic from reaching the NTP clients.

To fill this gap and the lack of nonce check, RFC 5905 [11] strongly suggests the use of cryptography to authenticate broadcast packets. Indeed, NTP’s current reference implementation requires symmetric-key cryptography, by default, for clients listening to broadcast packets. NTP’s symmetric cryptographic authentication appends an MD5 hash keyed with symmetric key k of the NTP packet contents m as $MD5(k||m)$ [12, pg 264] to the NTP packet in Figure 1; authenticated NTP packets also have a *key ID* that identifies the key used to authenticate the message.

³As we discussed in [9], NTP’s symmetric-key cryptography is not commonly used because the symmetric keys must be pre-configured manually; this can be quite cumbersome for public servers that must accept queries from arbitrary clients. (NIST, for example, distributes symmetric keys for its public servers via US mail or facsimile [2].) Moreover, NTP’s public-key cryptography (Autokey) is not recommended for use in the wild, see footnote 2.

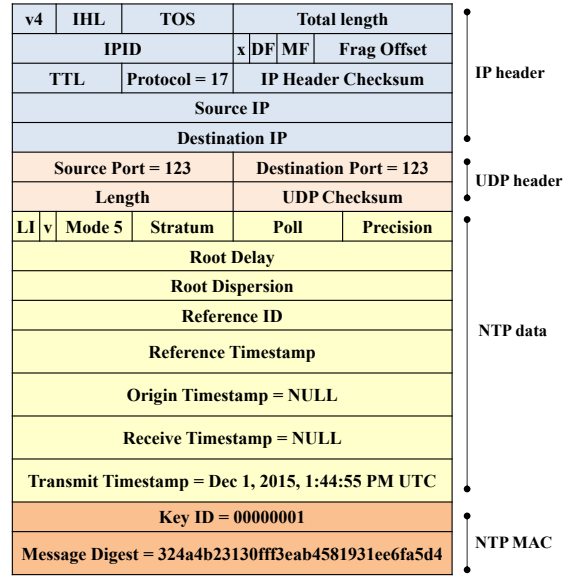

Figure 1: Mode 5 NTP Broadcast Packet.

In this paper, however, we present two attacks that show that NTP’s symmetric key cryptography does not provide sufficient protection for broadcast mode.

3. TIMESHIFTING ATTACKS

Should broadcast be robust to replay attacks? According to RFC 5905 [11], NTP’s “on-wire protocol ... resists replay of a server response packet.” This is supposed to be accomplished through what is called *TEST1* in the protocol specification: Upon receipt of an NTP response packet, the NTP client matches the transmit timestamp in the current packet to that of the last response packet it received; if the timestamp matches, it marks the packet as duplicate and drops it. However, we now show that because broadcast mode does not impose *TEST2*, then *TEST1* cannot provide sufficient protection against replay attacks, even when NTP packets are cryptographically authenticated.

Deja Vu: Our on-path time-sticking attack (CVE-2015-7973). Consider a man-in-the-middle (MiTM) attack, where the attacker is positioned between the server and the victim client, and can intercept and replay a packet and prevent onward transmission of the original packet, but does not possess the symmetric key that authenticates broadcast messages. We show that the protocol does not resist the following replay attack. The MiTM collects and records a contiguous sequence of server broadcast packets. (The attacker requires a sufficient number of these packets for the client to update its clock; this is because NTP requires a client to obtain between eight to hundreds of messages from a server before the client’s *clock discipline algorithms* synchronizes it to the server [11, Sec. 10-12].) He then replays this sequence of packets (while dropping the legitimate packets), over and over, to the victim client; the victim accepts the same time over and over, and thus gets stuck at a particular time. Notice that these are the authenticated packets from the broadcast server, and so they pass the authentication check on the client. Moreover, by replaying a *sequence* of packets, rather than just one packet, the attacker ensures that the replayed packets pass *TEST1*.

Why does this attack work? This attack highlights a weakness in RFC5905 [11]: In the absence of *TEST2*, *TEST1* doesn't actually prevent replay in general—it just prevents replay of the most recent packet. Our replay attack passes *TEST1* because the client only matches the current transmit timestamp with that of the last packet. This attack only applies to broadcast mode, since other modes (*e.g.*, client/server, symmetric, pool) do apply *TEST2*.

Experiment. We set up an ntpd v4.2.8p3 broadcast client and server using the configuration options *broadcastclient* and *broadcast IP_address_range* respectively. Another machine on the same network behaves as MiTM and collects 12 *mode 5* packets and stores them. The MiTM then drops the original *mode 5* packets to the victim and replays his previously collected set of *mode 5* packets, making sure to preserve their interarrival time. The victim accepts the time after getting sufficient samples required for a server to pass the clock discipline algorithms, gets into the 'STEP' mode⁴ and clears the state variables for this association. We continue this experiment for ≈ 4 hours and observe that the victim's system clock is stuck at the same time.

Implications of the attack. A MiTM can use a replay attack to make the victim client get stuck at a particular time value forever. Shifting time backwards has severe implications on security guarantees provided by various core Internet protocols, such as DNSSEC, BGP, TLS, and authentication services that use Kerberos; see our earlier paper [9].

Remark: Forging attacks are also possible. If the attacker is one of the clients on the broadcast network, or on an adjacent network that also gets broadcast packets from the same server, it then shares the same symmetric key with the server as the victim client. As [13, 16] have also noted, the attacker thus possesses the same key as the server and therefore can just forge authenticated NTP mode 5 packets and send them to the victim client. The attacker can then make the client stick to a particular time, or send the victim back/forward in time.

Remark: Delay attacks don't really work. One might wonder if a *delay attack* could be used for timeshifting, or to stick a client to a particular time. In a delay attack, the on-path attacker intercepts packets and delays them, in hope of pushing the client back in time. However, NTP has built-in mechanisms (*TEST11* [11]) to prevent this attack; specifically, NTP clients drop packets with a delay that approaches the "MAXDISTANCE" which is on the order of 1 second. Note that when an NTP client doesn't receive any valid timing information from the network, it just sticks to its local clock. So even if a delay attack were to work against NTP, it could not do much more than shift the client back in time by 1 second. Meanwhile, our Deja Vu attack forces the client to get stuck at a particular time (*e.g.*, Dec 1, 2015, 1:44:55 PM UTC) indefinitely.

4. DENIAL OF SERVICE ATTACKS

We now present an off-path denial-of-service attack that generically succeeds on any preemptable or ephemeral association that is cryptographically authenticated, including authenticated broadcast mode.

⁴An NTP client enters 'STEP' mode whenever it needs to shift its clock by more than 125ms but less than ≈ 16 min; our replay attack shifts the client back in time by more than 125ms, causing the client to enter STEP mode.

Preemptable and ephemeral associations. NTP's broadcast clients establish an *ephemeral association* upon receipt of an NTP mode 5 from a broadcast server; as discussed in Section 2, this association is automatically demobilized upon error or timeout. NTP also supports *preemptable* associations [10], which are also demobilized upon error or timeout. Preemptable associations are mobilized if the ntpd client has the keyword "preempt" to the line in its configuration file that establishes an association with a particular server. Alternatively, the ntpd client may be preconfigured with the *manycastclient* or *pool* [*pool_address*] options; in this case, the client establishes a preemptable association upon receiving a response to a server discovery packet.

Our off-path DoS attack (CVE-2015-7979). An off-path attacker can easily cause an error by sending a *mode 5* packet with bad cryptographic authentication (*e.g.*, wrong or mismatched key, incorrect message digest, *etc.*). The attacker sends one such error-causing packet for every legitimate response the client receives from the server, so that the client immediately tears down its association with the server. This way, the client never collects enough good NTP responses to allow its clock discipline algorithms to update its local clock. This is a denial-of-service attack on the client.

The only challenge is to learn the IP of the broadcast server used by the victim client. However, this turns out to be trivial as well. As we observed in [9, Sec V.C], the off-path attacker need only send the victim a timing query (a *mode 3* client request), and by default, the victim will respond with a timing response (a *mode 4* server response) that reveals the IP of the broadcast server in the *reference ID* field. This attack therefore exploits two issues in RFC5905 [11]: (1) the definition of ephemeral associations, and (2) information leakage in the reference ID field.

Experiment. We set up ntpd v4.2.8p3 broadcast client and server using the configuration options *broadcastclient* and *broadcast IP_address_range* respectively. Once the client is synchronized with the broadcast server, another machine which behaves as an off-path attacker sends badly-authenticated *mode 5* packet to the client. The client immediately tears down the association with the server and clears all the state variables. Next, the client receives the legitimate packet from the broadcast server and again mobilizes the association. The attacker again sends the bad *mode 5* packet and the client again tears down the association. The attacker keeps repeating this and the client never obtains enough consistent time samples from the server to allow it to update its system clock.

Implications. a) Even if cryptographic authentication is used, an off-path attacker can still spoof packets that will deny NTP service to a broadcast client. b) If the client is preconfigured to a bad timekeeper, or one of the servers' that the client is configured to is controlled/compromised by the attacker, then using this DoS attack, the attacker can pin the client to bad server that is controlled by him.

5. MEASUREMENT RESULTS

We use NTP's *peers* command to check for the presence of broadcast and other ephemeral and preemptable associations in the wild. As shown in Figure 2, NTP's *peers* command returns a list of all associations used by an NTP client; associations with a broadcast server are marked with a *b* or *B*, client/server associations are marked with a *u*,

etc.. ‘*’ is used to indicate the association that the client last took time from, and ‘+’ indicates an association that is a candidate for synchronization.

While the *peers* command provides a variety of useful information for network measurement, it’s also a great tool for adversarial network reconnaissance and DDoS amplification attacks [4]; for this reason, network operators commonly disable remote *peers* queries, or configure firewalls or other middleboxes to drop them. Moreover, while we conjecture broadcast mode is most common when both the clients and the broadcast server are behind a NAT, we are unable to scan clients behind a NAT. Therefore, it’s important to remember that our measurement results can only provide a hard lower bound on the number of broadcast/ephemeral/preemptable associations in the wild, rather than the *percentage* of broadcast-enabled clients. We suspect that even more broadcast clients are behind NATs and firewalls.

Our scan. We scanned the entire IPv4 address space using the *peers* command on 10-11 November 2015, and obtained responses from 4,443,118 IPv4 addresses. On 16-21 November 2015 we rescanned only the 4.4M responding IP addresses with NTP’s *peers* command, as well the *rv* command (which reveals useful information about the NTP client, including its version, build date, and the operating system it runs on), and the *as* command (which has useful information about each association used by the client). For this second scan we obtained responses from 3,716,362 IPv4 addresses; we consider only these addresses here.

Results. Of the 3.7M responding IPs, we found that 18,020 IPs have at least one broadcast association, and 1,767 IPs use multicast associations. We see 9,806 IPs that use broadcast associations exclusively, of which 7,556 IPs were synchronized to a broadcast server. The remaining 2,250 IP were unsynchronized and thus likely malfunctioning.

As an aside, we were also surprised to find many symmetric associations in the wild; 190,724 of the responding IPs had at least one symmetric association. Overall, we found 2,848,238 IPs that have at least one client/server associations, 77 IPs use multicast exclusively, 67383 IPs use symmetric associations exclusively, and 9806 use broadcast exclusively. This is a total of 2,925,504 IPs; for the rest of the IPs, their association status is “-” which may mean they are initializing, or using a local clock (*e.g.*, via GPS) rather than taking time from the Internet using NTP. Thus, while broadcast is not an especially popular mode of operation for NTP, we do find thousands of clients in the wild that rely upon it for time synchronization.

Who are these broadcast clients? Of the 18K IPs that have at least one broadcast association, 16,552 of them also responded to NTP’s *rv* query, and thus reveal information about their operating systems, ntpd version, and compile date. Most of these broadcast clients are running on unix (10,671 IPs) or ‘cisco’ devices (5,135 IPs). Also, out of 16.5K IPs that responded to the *rv* query, only 326 replied with the detailed ntpd version and compilation details (the rest merely say “ntpd version 4”). Of these, the majority (212 IPs) have been compiled between 2012 and 2015 inclusive. The most popular ntpd version that we found is 4.2.6p5@1.2349 (23%) which was released in December 2011, closely followed by 4.2.8@1.3265 (20%) which was released in December 2014, while 4.1.1c-rc1@1.836 (released in 2001) and 4.2.4p5-a (released in 2008) are 9% each. The bottom

```

```

Figure 2: Sample response to *peers* query.

line is that we do find evidence of recently maintained NTP implementations that use broadcast mode in the wild.

6. RECOMMENDATIONS

1) Ephemeral and preemptable associations considered harmful. Our denial-of-service attack from Section 4 points to a serious problem with the notion of ephemeral and preemptable associations; namely, that an off-path attacker can easily forge a packet that can tear down an association. Even though an ephemeral association can easily be reestablished, the attacker can quickly tear it down again before the client has the chance to update its clock. For this reason, we suggest that NTP does NOT tear down ephemeral associations upon receipt of a malformed packet; instead, the malformed packet should just be dropped, while the association remains in place. While this recommendation is fairly easy to implement, it does require making changes to RFC5905 [11].

2) Prevent replay in broadcast mode. As others have pointed out [13, 16], NTP’s broadcast mode should contain a robust mechanism for preventing replay attacks. *TEST1* is insufficient, since it only checks if the most recent packet has been replayed. One solution is to require authenticated mode 5 NTP packets to include an incrementing counter (*e.g.*, in the extension field). Alternatively, the MAC computed on the broadcast packet could become a hash chain; that is, the MAC on packet p_i should be computed over the contents of packet p_i concatenated with the MAC on packet p_{i-1} . The former suggestion, however, requires changes to the NTP packet formats, while the latter suggestion requires changes on both the client side *and* the server side.

Another idea is to use the transmit timestamp field in the mode 5 packet (Figure 1) as an incrementing counter; to do this, the broadcast client would need to ensure that the transmit time is monotonically increasing. This idea has a nice backwards-compatibility property: only clients that wish to enforce this check must do so, and no changes are required on the server side. This recommendation also requires changes to RFC5905 [11], and has been implemented in ntpd v4.2.8p6 following disclosure of our work.

3) Only the broadcast server should be able to sign broadcast packets. As others have pointed out [13, 16], the broadcast servers’ symmetric key should NOT be distributed to all its clients; as we noted in Section 3, this allows clients to trivially forge packets from the server. Instead, the only entity that should be able to sign broadcast (mode 5) packets is the broadcast server itself. Unlike the previous two recommendations, however, which are fairly simple to implement today, some more thought is required before it becomes clear how to achieve this last recommendation. The crucial issue is that the cryptographic computations performed on each packet must be sufficiently fast

to avoid harming NTP's clock synchronization algorithms. As such, we cannot just digitally sign every NTP broadcast packet with a standard public-key digital signature scheme like RSA or ECDSA.

NTS and TESLA. One approach, taken by a new Internet draft for the "Network Time Security protocol (NTS)", seeks to implement recommendations (2) and (3) above through a modified version of TESLA [14]. TESLA uses public-key cryptography to ensure that a server is the only entity that can authenticate broadcast messages, but that the authenticators on individual packets can be computed and validated using fast symmetric cryptography. With TESLA, a packet containing a message and its MAC is broadcast to clients immediately, while the secret key for the MAC is broadcast after some pre-determined time interval. As such, TESLA requires loose time synchronization between the broadcast server and its client, and so using TESLA in the context of NTP creates a circular dependency on time. NTS suggests avoiding this circular dependency by using an authenticated unicast association to achieve the loose synchronization between the server and each of its clients. This, however, once again requires pairwise associations between server and each client, and server and client must also share a symmetric cryptographic key; this may defeat the purpose of using the broadcast mode in the first place.

Indeed, as indicated by a recent survey [5], many known cryptographic techniques for authenticating broadcast communications rely on some sort of time-released key mechanism, and therefore require loose time synchronization.

Recommendations for users. It is evident that significant effort is required before recommendation (3) can be implemented. Thus, we currently recommend *against* the use of broadcast mode, unless the broadcast server and all its clients are on a trusted (*i.e.*, firewalled) network.

7. CONCLUSION

Our analysis highlights the difficulty of designing robust cryptographic authentication for NTP's broadcast mode. One might be tempted to dismiss broadcast mode altogether, by arguing that broadcast mode is a legacy from the past that is largely unused today. Our measurements, however, indicate that this is not the case; while broadcast mode is not especially popular, we do find thousands of NTP clients in the wild that have broadcast associations. Thus, we believe that the community should take another careful look at authentication for NTP's broadcast mode. Indeed, it remains an interesting open problem to find a scheme that can cryptographically authenticate NTP's broadcast mode in a way that is both fast and secure, and does not introduce a circular dependency on time.

Acknowledgements

We are especially grateful to Matt Van Gundy for collaboration and for leading the disclosure of these results. We thank Jonathan Gardner, Matthew Street, Stephen Gray and Hai Li from Cisco's ASIG team for useful discussions, Jared Mauch for performing the initial scan of the IPv4 address space with NTP's *peers* command, David Mills for suggesting we look into broadcast mode, and the Network Time Foundation and NTPsec for deploying patches. This research was supported, in part, by NSF awards 1347525, 1414119, 1012910 and a gift from Cisco.
